

1 Average segregation time

As mentioned earlier, the segregation time of $n\%$ is defined as the number of generations until at least $n\%$ of the population on a board lives in homogenous groups. Where person i is said to live homogenous if for any neighbour j of i , we have $\text{Type}(j) = \text{Type}(i)$.

This gives immediate rise to questions concerning the relation between the choice of n and the average segregation time at $n\%$. Furthermore, it is unclear if segregation at $n\%$ is guaranteed before a board reaches an equilibrium and what the effect is of the happiness boundary on the existence of a segregation time.

To research any of the given questions, we will first have to formalise our choices of board as well as the questions proposed.

1.1 Formalisations

Prior to starting any test or properly formalising our research questions however, we note that segregation at $n\%$ does not necessarily have to happen: If we consider $n = 100$ on the standard board with happiness $1/3$. We will nearly never have total segregation before the board reaches an equilibrium. Therefore one might instead consider the average fraction of segregation at equilibrium, for any given happiness fraction.

Furthermore, the average segregation time as function of the segregation fraction should theoretically be a strictly increasing function since for any given board we have:

$$\begin{aligned} n\% \text{ lives in homogenous groups after } k \text{ generations} &\Rightarrow \\ m\% \text{ lives in homogenous groups after } k \text{ generations, for any } 0 \leq m \leq n \end{aligned}$$

Having noted these facts, we can now properly formalise the research questions.

The following two questions are proposed:

1. ***What is the relation between the average segregation time and n .***
2. What is the average segregated fraction of the population after a board reaches equilibrium for given choices of happiness.

To establish results regarding these questions, we consider different setups in testings. We will be testing two different boards. The first board to be analysed is the standard board. The second board is a larger "4-Type" board. The details are specified below:

Table 1: My caption

	Standard Board	4-Type Board
Number of types:	2	4
Length:	8	10
Width:	8	10
Happiness:	1	1
Population per type:	20	16

The 4-Type board is constructed to maintain the same ratio of inhabited and uninhabited spots as the standard board. The choice of happiness on these boards is 1 unlike the usual $\frac{1}{3}$. This guarantees that for any $n \leq 100$, segregation at $n\%$ takes place prior to the board reaching an equilibrium. To observe the average segregation time $n\%$ for any n , 500 simulations will be ran per board and averaged out in order to give an approximation for the average segregation time at $n\%$. Likewise the average segregated fraction will be estimate by the average of the segregated fraction of an equilibrium from 500 simulations with given happiness q .

1.2 Results

The results regarding the first question are shown below:

Figure 1: Average segregation time on the standard board

Most notable of figure 1 is that it is neither linear nor exponential, which is what one might initially expect. Instead, it appears to be partially exponential and partially linear. From the figure, we note that the average segregation time increases fastest between 0.4 and 0.5. Which is to say that it takes three times longer for 50% of the population to live in homogenous groups than for 40%.

Also note that the 'lift off' is approximately at $\frac{1}{3}$, but it is unlikely that this has anything to do with the standard happiness rule of $\frac{1}{3}$.

Partial explanation. The first part of the graph is easy to understand. Because of the initial random placement of the individuals, the odds are quite good that few individuals are already homogenous. For the second part between 0.4 and 0.5, it appears to take a relatively long time to transform from the initial chaos to 50% segregation. A 'boundary' has to be taken, comparable with the activation energy for chemical reactions.

If 50% segregation has been reached, it becomes more easy to segregate even further, because individuals can easily move from one homogenous group (of the other type) to another (of their own type), which explains the part between 50% and 70%. One'd expect this to continue and it'd be done in another one or two generations, but with 70% segregation, it gets harder for individuals to move to a location that is homogenous.

Next, we consider the same question but this time for the 4-Type board, and we get the following result.

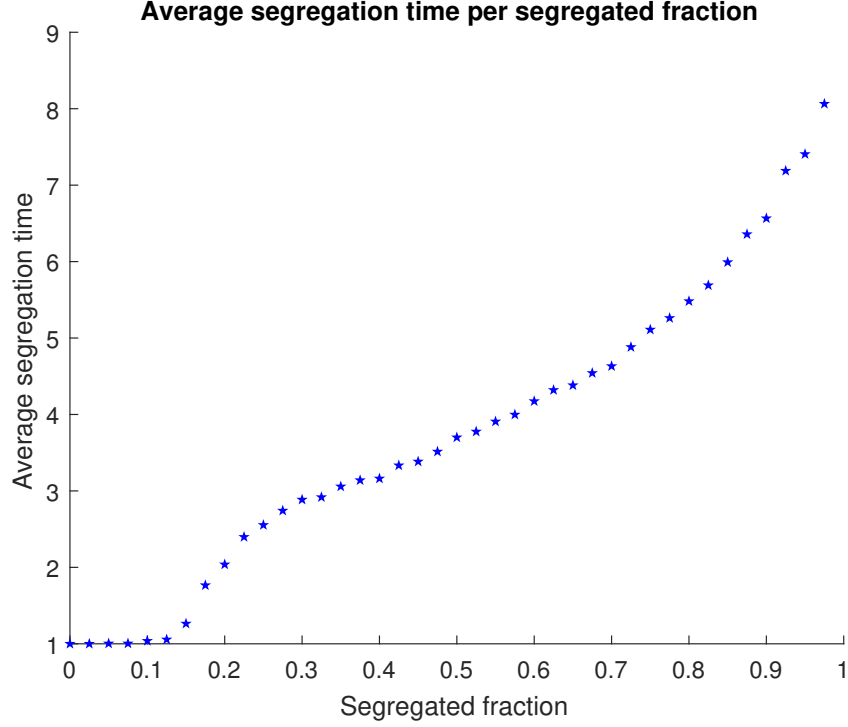

Figure 2: Average segregation time on the 4-Type board

The most notable difference between this figure and the figure 1 is that the 'lift off' lies much earlier than in figure 1. Now based on the number of types, you'd expect this to be around half as soon.

Now why is the fraction at which figure 2 lifts off not exactly half, but sooner than the lift off of figure 1? Although this difference feels intuitive, we will give a formal explanation. Consider the probability that any individual i has a neighbours of the same type, and no neighbours of another type, given $k - a$ empty spots, where k is the maximum number of possible neighbours for the location of i . In the basic model, this probability equals

$$p_b = \frac{19}{39} \frac{18}{38} \cdots \frac{19-a}{39-a} = \frac{\frac{19!}{(19-a)!}}{\frac{39!}{(39-a)!}} = \frac{19!(39-a)!}{39!(19-a)!}$$

In the 4-Type model, this probability is

$$p_4 = \frac{15!(63-a)!}{63!(15-a)!}$$

which is less than half of p_b .

Also note that an individual is more likely to be homogenous if it is placed at a corner or edge. This is because a corner or edge spot has less possible neighbours than an interior spot, thus increasing the probability of only having neighbours of your own type. The 4-Type board has relatively fewer edge positions in comparison to the standard board. This effect also decreases the fraction of segregation prior to displacement of individuals. However the people/boardspace ratio is almost the same in both models and thus should not have too much of an impact on the results. The number of types however results in two key differences. The first being the increased number of generations. The second (and more interesting) difference is that this graph lifts off earlier, which is explained above. This along with the first difference, results in a smoother curve which appears to resemble a cubic relation.

Figure 3: Average segregated fraction as a result of happiness on the standard board

Figure 3 displays three scattered values. The red and green dots represent the minimum and maximum segregated fraction of 500 boards for the given happiness. Notable in this picture is that the average segregated value is greater than the happiness. Another thing worth noting is that the segregated fractions tend to appear in different groups separated by relatively large percentages.

2 conclusion?
